Recall: What is a Distributed System?

A distributed system is one in which the failure of a computer you didn’t even know existed can render your own computer unusable.

Leslie Lamport, The Godfather of Distributed Systems
Recall: Centralised vs Distributed Systems

Considered a single computer! All computation was done on the local computer in isolation.

The world is a large distributed system.
Recall: Two types of distributed systems

**Client/Server Model**
- One or more server provides services to clients
- Clients make remote procedure calls to server
- Server serves requests from clients

**Peer-to-Peer Model**
- Each computer acts as a peer
- No hierarchy or central point of coordination
- All-way communication between peers through gossiping
Recall: The promise of distributed systems

**Availability**
Proportion of time system is in functioning condition
=> One machine goes down, use another

**Fault-tolerance**
System has well-defined behaviour when fault occurs
=> Store data in multiple locations

**Scalability**
Ability to add resources to system to support more work
⇒ Just add machines when need more storage/processing power

**Transparency**
The ability of the system to mask its complexity behind a simple interface
CS162 Students Vs Elon Musk

THE

SHOWDOWN
Do you believe this?

**Elon Musk** @elonmusk · 1d
Btw, I’d like to apologize for Twitter being super slow in many countries. App is doing >1000 poorly batched RPCs just to render a home timeline!

**Popeska** @Popeska · Nov 14
Repeating @elonmusk and @sampullara
The batching is done server-side where the initial client request doesn't matter - GraphQL resolves the request across the microservices and then sends it back. The internal graph is the same regardless of request origin

Same app in US takes ~2 secs to refresh (too long), but ~20 secs in India, due to bad batching/verbose comms. Actually useful data transferred is low.

Topic roadmap

Distributed File Systems

Peer-To-Peer System: The Internet

Distributed Data Processing

Coordination (Atomic Commit and Consensus)
Distributed File Systems

Transparent access to files stored on a remote disk

*Mount* remote files into your local file system
- Directory in local file system refers to remote files
- e.g., /users/jane/prog/foo.c on laptop actually refers to /prog/foo.c on crooks.cs.berkeley.edu

**Naming Choices:**
- [Hostname,localname]: Filename includes server
- A global name space: Filename unique in “world”
Virtual Filesystem Switch

Virtual abstraction of file system
- Provides virtual superblocks, inodes, files, etc
- Compatible with a variety of local and remote file systems

VFS allows the same system call interface (the API) to be used for different types of file systems
- The API is to the VFS interface, rather than any specific type of file system

```c
inf = open("/floppy/TEST", O_RDONLY, 0);
outf = open("/tmp/test",
           O_WRONLY|O_CREAT|O_TRUNC, 0600);
  do {
    i = read(inf, buf, 4096);
    write(outf, buf, i);
  } while (i);
  close(outf);
  close(inf);
```
Example Linux mounting tree
Four primary object types for VFS:
- superblock object: represents a specific mounted filesystem
- inode object: represents a specific file
- dentry object: represents a directory entry
- file object: represents open file associated with process

May need to fit the model by faking it
Remote Disk: Reads and writes forwarded to server. Use Remote Procedure Calls (RPC) to translate file system calls into remote requests.

Advantage: Server provides consistent view of file system to multiple clients.

Problems? Performance!
- Going over network is slower than going to local memory
- Lots of network traffic/not well pipelined
- Server can be a bottleneck
Use of caching to reduce network load

Idea: Use caching to reduce network load
   - In practice: use buffer cache at source and destination

Advantage: if open/read/write/close can be done locally, don’t need to do any network traffic...fast!

Problems:
   - Failure:
     » Client caches have data not committed at server
   - Cache consistency! Client caches not consistent with server/each other
Dealing with Failures

What if server crashes? Can client wait until it comes back and just continue making requests?
- Changes in server’s cache but not in disk are lost

What if there is shared state across RPC’s?
- Client opens file, then does a seek
- Server crashes
- What if client wants to do another read?

Similar problem: What if client removes a file but server crashes before acknowledgement?
Stateless Protocol: A protocol in which all information required to service a request is included with the request.

Idempotent Operations – repeating an operation multiple times is same as executing it just once (e.g., storing to a mem addr.)

Client: timeout expires without reply, just run the operation again (safe regardless of first attempt)

Recall HTTP: Also a stateless protocol
- Include cookies with request to simulate a session
Case Study: Network File System (NFS)

It’s an open world!

Three Layers for NFS system

**UNIX file-system interface:** open, read, write, close calls + file descriptors

**VFS layer:** distinguishes local from remote files
  » Calls the NFS protocol procedures for remote requests

**NFS service layer:** bottom layer of the architecture
  » Implements the NFS protocol
NFS Protocol: RPC for file operations on server
- Reading/searching a directory
- Manipulating links and directories
- Accessing file attributes/reading and writing files

Write-through caching: Modified data committed to server’s disk before results are returned to the client
- Lose some of the advantages of caching
- Time to perform write() can be long
- Need some mechanism for readers to eventually notice changes! (more on this later)

NSF2: Every write persisted.
NSF3: Open-to-close consistency
NFS servers are stateless; each request provides all arguments require for execution

- E.g. reads include information for entire operation, such as `ReadAt(inumber,position)`, not `Read(openfile)`
- No need to perform network `open()` or `close()` on file – each operation stands on its own

**Idempotent:** Performing requests multiple times has same effect as performing them exactly once

- Example: Read and write file blocks: just re-read or re-write file block – no other side effects
- Example: What about “remove”? NFS does operation twice and second time returns an advisory error
### NFS Continued

# NFS Continued

<table>
<thead>
<tr>
<th>Client</th>
<th>Server</th>
</tr>
</thead>
</table>
| fd = open("/foo", ...);  
Send LOOKUP (rootdir FH, "foo") | Receive LOOKUP request  
look for "foo" in root dir  
return foo’s FH + attributes |
| Receive LOOKUP reply  
allocate file desc in open file table  
store foo’s FH in table  
store current file position (0)  
return file descriptor to application | |
| **read(fd, buffer, MAX);**  
Index into open file table with fd  
get NFS file handle (FH)  
use current file position as offset  
Send READ (FH, offset=0, count=MAX) | |
| Receive READ request  
use FH to get volume/inode num  
read inode from disk (or cache)  
compute block location (using offset)  
read data from disk (or cache)  
return data to client | |
| Receive READ reply  
update file position (+bytes read)  
set current file position = MAX  
return data/error code to app | |
| **read(fd, buffer, MAX);**  
Same except offset=MAX and set current file position = 2*MAX | |
Failure Model: Transparent to client system

- Is this a good idea? What if you are in the middle of reading a file and server crashes?

- Options (NFS Provides both):
  » Hang until server comes back up (next week?)
  » Return an error. (Of course, most applications don’t know they are talking over network)
NFS Architecture

Client

- system-calls interface
  - VFS interface
    - other types of file systems
    - UNIX file system
      - NFS client
        - RPC/XDR
          - disk
    - NFS server
      - RPC/XDR
        - disk
  - network

Server

- VFS interface
  - UNIX file system

NFS protocol: weak consistency

- Client polls server periodically to check for changes
  - Polls server if data hasn’t been checked in last 3-30 seconds (exact timeout is tunable parameter).
  - Thus, when file is changed on one client, server is notified, but other clients use old version of file until timeout.

What if multiple clients write to same file?

- In NFS, can get either version (or parts of both)
- Completely arbitrary!
NFS Cache consistency
What sort of cache coherence might we expect? – i.e. what if one CPU changes file, and before it’s done, another CPU reads file?

Example: Start with file contents = “A”

Client 1: Read: gets A  Write B  Read: parts of B or C
Client 2: Read: gets A or B  Write C
Client 3: Read: parts of B or C

Time
What would we actually want?

- Assume we want distributed system to behave exactly the same as if all processes are running on single system
  » If read finishes before write starts, get old copy
  » If read starts after write finishes, get new copy
  » Otherwise, get either new or old copy

- For NFS:
  » If read starts more than 30 seconds after write, get new copy; otherwise, could get partial update
NFS Pros:
- Simple, Highly portable

NFS Cons:
- Sometimes inconsistent!
- Doesn’t scale to large # clients
  » Must keep checking to see if caches out of date
  » Server becomes bottleneck due to polling traffic
Case study: The Internet

The Internet is the largest distributed system that exists!

Many different applications
- Email, web, P2P, etc.

Many different operating systems and devices

Many different network styles and technologies
- Wireless, wired, optical

How do we organize this mess
- Layering & end-to-end principle
Introduce intermediate layers that provide set of abstractions for various network functionality & technologies
- A new app/media implemented only once

Goal: Reliable communication channels on which to build distributed applications
The Internet: The *hourglass*

"Narrow waist" facilitates interoperability

Layers "abstract" away hardware so that upper layers are agnostic to lower layers

=> Sound familiar?
The Internet: Implications of Hourglass

**Single Internet-layer module (IP):**

- Allows arbitrary networks to interoperate
  - Any network technology that supports IP can exchange packets

- Allows applications to function on all networks
  - Applications that can run on IP can use any network

- Supports simultaneous innovations above and below IP
  - But changing IP itself, i.e., IPv6, very involved
The Internet: Drawbacks of Layering

Layer N may duplicate layer N-1 functionality
- E.g., error recovery to retransmit lost data

Layers may need same information
- E.g., timestamps, maximum transmission unit size

Layering can hurt performance
- E.g., hiding details about what is really going on

Some layers are not always cleanly separated
- Inter-layer dependencies for performance reasons
- Some dependencies in standards (header checksums)
End-To-End Argument

Hugely influential paper:
- “End-to-End Arguments in System Design” by Saltzer, Reed, and Clark (‘84)

“Sacred Text” of the Internet
- Endless disputes about what it means
- Everyone cites it as supporting their position

Simple Message: Some types of network functionality can only be correctly implemented end-to-end
- Reliability, security, etc.

Hosts cannot rely on the network help to meet requirement, so must implement it themselves
Example: Reliable File Transfer

**Solution 1:** make each step reliable, and then concatenate them

**Solution 2:** end-to-end check and try again if necessary
Solution 1 is incomplete
What happens if memory is corrupted?
Receiver has to do the check anyway!

Solution 2 is complete
Full functionality can be entirely implemented at application layer with no need for reliability from lower layers

Is there any need to implement reliability at lower layers?
Well, it could be more efficient
Implementing complex functionality in the network:
- Doesn’t always reduce host implementation complexity
- Does increase network complexity
- Probably imposes delay and overhead on all applications, even if they don’t need functionality

However, implementing in network can enhance performance in some cases
  – e.g., very lossy link
Conservative Interpretation of E2E

Don’t implement a function at the lower levels of the system unless it can be completely implemented at this level

Or: Unless you can relieve the burden from hosts, don’t bother
Moderate Interpretation

Think twice before implementing functionality in the network

If hosts can implement functionality correctly, implement it in a lower layer only as a performance enhancement

But do so only if it does not impose burden on applications that do not require that functionality

This is the interpretation we are using
